### EE4704 Image Processing and Analysis

### Tutorial Set C – Solutions

#### Question 1

### Part (a)

Compare the first number in the initial list with the second number. If the first number is smaller, interchange the positions; otherwise compare the second number with the third, and so on. At the end of the first iteration, the smallest number wil be found at the bottom of the list. Repeat the procedure for the next iteration. (See illustration below.)

Suppose there are N numbers in the list (where  $N = k^2$ ).

Obtaining the smallest number requires (N-1) comparisons

Obtaining the 2nd smallest number requires (N-2) comparisons

Obtaining the 3rd smallest number requires (N-3) comparisons and so on.

Since we are only interested in the median value, there is no need to sort the entire list. The number of comparisons required to determine the median is

$$C_1 = (N-1) + (N-2) + \dots + \frac{1}{2}(N-1)$$
 (1)

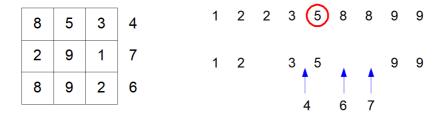

$$= \frac{3}{8}(N^2 - 1) \tag{2}$$

$$= \frac{3}{8}(k^4 - 1) \tag{3}$$

(Eq. (1) is an arithmetic series whose sum can be obtained with a standard fromula.)

### Part (b)

As the window is moved from pixel to pixel, discard those pixel values that are no longer in the window, and insert the new pixel values in the appropriate places in the sequence.

Assume that the initial set of pixel intensities have already been fully sorted. Each time we shift the window, we drop k numbers and take in k new numbers. In the worst case:

the 1st new number is compared with (N-k) numbers

the 2nd new number is compared with (N-k)+1 numbers

the kth new number is compared with (N-k)+(k-1) numbers The total number of comparisons is

$$C_2 = k(N-k) + \frac{k}{2}(k-1)$$
  
=  $\frac{k}{2}(k-1)(2k+1)$ 

# Part (c)

$$k = 3 \quad \frac{C_1}{30} \quad \frac{C_2}{21} \quad \frac{C_2/C_1}{0.70}$$

$$k = 5 \quad 234 \quad 110 \quad 0.47$$

$$k = 7 \quad 900 \quad 315 \quad 0.35$$

### Question 3

## Part (a)

The output of the MMSE filter is:

$$g(x,y) = f(x,y) - \frac{\sigma_{\eta}^{2}}{\sigma_{l}^{2}} [f(x,y) - m_{l}(x,y)]$$

= noise variance

= local variance (in the window under consideration)

local mean (in the window under consideration)

Consider a  $3 \times 3$  neighbourhood centred at a noise point; one out of nine pixels is an extreme value (255). Compare this local variance with the noise variance, where the latter is determined by the fact that 0.01 (or 1 in 100) of the pixels is a noise pixel (of value 255). Hence, it is likely that the local variance will be much greater than the noise variance:

$$\sigma_l^2 \gg \sigma_\eta^2$$

 $\sigma_l^2 \gg \sigma_\eta^2 \end{red}$  Thus the output at this point is

$$g(x,y) \approx f(x,y)$$

i.e., there is very little filtering of the noise value. Hence, the MMSE filter will have very little effect on the image.

### Part (b)

The image formed by averaging K different noisy images is

$$\bar{g}(x,y) = \frac{1}{K} \sum_{t=1}^{K} g_t(x,y)$$

Consider a pixel at (p,q). Suppose  $g_1(p,q) = 255$ , i.e., pixel (p,q) in the first image is a noise pixel. This value of 255 is likely to be very different from the noise-free pixel value, f(p,q). For example, if we have 10 frames,

$$g_1(p,q) = 255$$
  
 $g_2(p,q) = f(p,q) = 100$   
 $g_3(p,q) = f(p,q) = 100$   
 $g_4(p,q) = f(p,q) = 100$   
...

 $\bar{g}(p,q) = \frac{1}{10}(255 + 100 + 100 + ...) = 116$ 

which is still substantially different from the noise-free value of 100.

Hence, many image frames will be required before  $\bar{g}(x,y)$  approaches f(x,y), i.e., image averaging is not suitable.
